2ED2103S06F
650 V half bridge gate driver with integrated bootstrap diode

Features
- Unique Infineon Thin-Film-Silicon On Insulator (SOI)-technology
- Negative VS transient voltage immunity of -100 V
- Floating channel designed for bootstrap operation
- Operating voltages (VS node) up to +650 V
- Maximum bootstrap voltage (VB node) of +675 V
- Integrated ultra-fast, low resistance bootstrap diode
- Logic operational up to -11 V on VS Pin
- Negative voltage tolerance on inputs of -5 V
- Independent under voltage lockout for both channels
- Schmitt trigger inputs with hysteresis
- 3.3 V, 5 V and 15 V input logic compatible
- Maximum supply voltage of 25 V
- DSO-8 package
- RoHS compliant

Potential applications
Driving IGBTs, enhancement mode N-Channel MOSFETs in various power electronic applications.
Typical Infineon recommendations are as below:
- Motor drives, general purpose inverters having TRENCHSTOP™ IGBT6 or 600 V EasyPACK™ modules
- Refrigeration compressors, induction cookers, other major home appliances having RCD series IGBTs or TRENCHSTOP™ family IGBTs or their equivalent power stages
- Battery operated small home appliances such as power tools, vacuum cleaners using low voltage OptiMOS™ MOSFETs or their equivalent power stages
- Totem pole, half-bridge and full-bridge converters in offline AC-DC power supplies for industrial SMPS having high voltage CoolMOS™ super junction MOSFETs or TRENCHSTOP™ H3 and WR5 IGBT series
- High power LED and HID lighting having CoolMOS™ super junction MOSFETs
- Electric vehicle (EV) charging stations and battery management systems
- Driving 650 V SiC MOSFETs in above applications

Product validation
Qualified for industrial applications according to the relevant tests of JEDEC47/20/22

2ED2103S06F

650V half bridge driver with integrated bootstrap diode

Description

The 2ED2103S06F is a high voltage, high speed power MOSFET and IGBT driver with independent high and low side referenced output channels. Based on Infineon’s SOI-technology there is an excellent ruggedness and noise immunity with capability to maintain operational logic at negative voltages of up to -11 V_{SC} on VS pin (V_{CC} = 15 V) on transient voltages. There are not any parasitic thyristor structures present in the device, hence no parasitic latch up may occur at all temperature and voltage conditions. The logic input is compatible with standard CMOS or LSTTL output, down to 3.3 V logic. The output drivers feature a high pulse current buffer stage designed for minimum driver cross-conduction. The floating channel can be used to drive an N-channel power MOSFET, SiC MOSFET or IGBT in the high side configuration, which operate up to 650 V.

4 Electrical parameters

4.1 Absolute maximum ratings

Absolute maximum ratings indicate sustained limits beyond which damage to the device may occur. All voltage parameters are absolute voltages referenced to COM unless otherwise stated in the table. The thermal resistance and power dissipation ratings are measured under board mounted and still air conditions.

Note 1: In case V_CC > V_S there is an additional power dissipation in the internal bootstrap diode between pins V_CC and V_S in case of activated bootstrap diode.

4.2 Recommended operating conditions

For proper operation, the device should be used within the recommended conditions. All voltage parameters are absolute voltages referenced to COM unless otherwise stated in the table. The offset rating is tested with supplies of (V_CC – COM) = (V_B – V_S) = 15 V.

5 Application information and additional details

5.1 IGBT / MOSFET gate drive

The 2ED2103S06F HVIC is designed to drive MOSFET or IGBT power devices. Figure 4 and Figure 5 illustrate several parameters associated with the gate drive functionality of the HVIC. The output current of the HVIC, used to drive the gate of the power switch, is defined as $I_O$. The voltage that drives the gate of the external power switch is defined as $V_{HO}$ for the high-side power switch and $V_{LO}$ for the low-side power switch; this parameter is sometimes generically called $V_{OUT}$ and in this case does not differentiate between the high-side or low-side output voltage.

![HVIC Sourcing current](image)

![HVIC Sinking current](image)

5.2 Switching and timing relationships

The relationships between the input and output signals of the 2ED2103S06F are illustrated below in Figure 6 and Figure 7. From these figures, we can see the definitions of several timing parameters (i.e. $t_{ON}$, $t_{OFF}$, $t_R$, and $t_F$) associated with this device.

![Switching timing diagram](image)

![Input/output logic diagram](image)
5.3 Deadtime

This family of HVICs features integrated deadtime protection circuitry. The deadtime is fixed for 2ED2103S06F. The deadtime feature inserts a time period (a minimum deadtime) in which both the high- and low-side power switches are held off; this is done to ensure that the power switch being turned off has fully turned off before the second power switch is turned on. This minimum deadtime is automatically inserted whenever the external deadtime is shorter than internal deadtime; external deadtimes larger than internal deadtime are not modified by the gate driver. Figure 8 illustrates the deadtime period and the relationship between the output gate signals.

![Figure 8: Deadtime waveform definition](image)

5.4 Matched propagation delays

The 2ED2103S06F is designed with propagation delay matching circuitry. With this feature, the IC’s response at the output to a signal at the input requires approximately the same time duration (i.e., $t_{on}$, $t_{off}$) for both the low-side channels and the high-side channels; the maximum difference is specified by the delay matching parameter ($MT$). The propagation turn-on delay ($t_{on}$) of the 2ED2103S06F is matched to the propagation turn-on delay ($t_{off}$).

![Figure 9: Delay matching waveform definition](image)

5.5 Input logic compatibility

The input pins are based on a TTL and CMOS compatible input-threshold logic that is independent of the Vcc supply voltage. With typical high threshold ($V_{IH}$) of 2.1 V and typical low threshold ($V_{IL}$) of 0.9 V, along with very little temperature variation as summarized in Figure 10, the input pins are conveniently driven with logic level PWM control signals derived from 3.3 V and 5 V digital power-controller devices. Wider hysteresis (typically 0.9 V) offers enhanced noise immunity compared to traditional TTL logic implementations, where the hysteresis is...
typically less than 0.5 V. 2ED210x family also features tight control of the input pin threshold voltage levels which eases system design considerations and ensures stable operation across temperature. The 2ED210x features floating input protection wherein if any of the input pin is left floating, the output of the corresponding stage is held in the low state. This is achieved using pull-down resistors on all the input pins (HIN, LIN) as shown in the block diagram. The 2ED210x family has input pins that are capable of sustaining voltages higher than the bias voltage applied on the Vcc pin of the device.

![Figure 10: HIN & LIN input thresholds](image)

### 5.6 Undervoltage lockout

This IC provides undervoltage lockout protection on both the Vcc (logic and low-side circuitry) power supply and the Vbs (high-side circuitry) power supply. Figure 11 is used to illustrate this concept; Vcc (or Vbs) is plotted over time and as the waveform crosses the UVLO threshold (VccUV+ or VbsUV+) the undervoltage protection is enabled or disabled.

Upon power-up, should the Vcc voltage fail to reach the VccUV+ threshold, the IC won’t turn-on. Additionally, if the Vcc voltage decreases below the VccUV- threshold during operation, the undervoltage lockout circuitry will recognize a fault condition and shutdown the high and low-side gate drive outputs.

Upon power-up, should the Vbs voltage fail to reach the VbsUV+ threshold, the IC won’t turn-on. Additionally, if the Vbs voltage decreases below the VbsUV- threshold during operation, the undervoltage lockout circuitry will recognize a fault condition, and shutdown the high-side gate drive outputs of the IC.

The UVLO protection ensures that the IC drives the external power devices only when the gate supply voltage is sufficient to fully enhance the power devices. Without this feature, the gates of the external power switch could be driven with a low voltage, resulting in the power switch conducting current while the channel impedance is high; this could result in very high conduction losses within the power device and could lead to power device failure.

![Figure 11: UVLO protection](image)
5.7 Bootstrap diode

An ultra-fast bootstrap diode is monolithically integrated for establishing the high side supply. The differential resistor of the diode helps to avoid extremely high inrush currents when initially charging the bootstrap capacitor. The integrated diode with its resistance helps save cost and improve reliability by reducing external components as shown below Figure 12 and Figure 13.

The low ohmic current limiting resistor provides essential advantages over other competitor devices with high ohmic bootstrap structures. A low ohmic resistor such as in the 2ED210x family allows faster recharging of the bootstrap capacitor during periods of small duty cycles on the low side transistor. The bootstrap diode is usable for all kind power electronic converters. The bootstrap diode is a real pn-diode and is temperature robust. It can be used at high temperatures with a low duty cycle of the low side transistor.

The bootstrap diode of the 2ED210x family works with all control algorithms of modern power electronics, such as trapezoidal or sinusoidal motor drives control.

5.8 Calculating the bootstrap capacitance $C_{BS}$

Bootstrapping is a common method of pumping charges from a low potential to a higher one. With this technique a supply voltage for the floating high side sections of the gate drive can be easily established according to Figure 14. This method has the advantage of being simple and low cost but may force some limitations on duty-cycle and on-time since they are limited by the requirement to refresh the charge in the bootstrap capacitor. Proper capacitor choice can reduce drastically these limitations.
When the low side MOSFET turns on, it will force the potential of pin $V_S$ to GND. The existing difference between the voltage of the bootstrap capacitor $V_{CBS}$ and $V_{CC}$ results in a charging current $I_{BS}$ into the capacitor $C_{BS}$. The current $I_{BS}$ is a pulse current and therefore the ESR of the capacitor $C_{BS}$ must be very small in order to avoid losses in the capacitor that result in lower lifetime of the capacitor. This pin is on high potential again after low side is turned off and high side is conducting current. But now the bootstrap diode $D_{BS}$ blocks a reverse current, so that the charges on the capacitor cannot flow back to the capacitor $C_{CC}$. The bootstrap diode $D_{BS}$ also takes over the blocking voltage between pin $V_S$ and $V_{CC}$. The voltage of the bootstrap capacitor can now supply the high side gate drive sections. It is a general design rule for the location of bootstrap capacitors $C_{BS}$, that they must be placed as close as possible to the IC. Otherwise, parasitic resistors and inductances may lead to voltage spikes, which may trigger the undervoltage lockout threshold of the individual high side driver section. However, all parts of the 2ED210x family, which have the UVLO also contain a filter at each supply section in order to actively avoid such undesired UVLO triggers.

The current limiting resistor $R_{BS}$ according to Figure 14 reduces the peak of the pulse current during the low side MOSFET turn-on. The pulse current will occur at each turn-on of the low side MOSFET, so that with increasing switching frequency the capacitor $C_{BS}$ is charged more frequently. Therefore a smaller capacitor is suitable at higher switching frequencies. The bootstrap capacitor is mainly discharged by two effects: The high side quiescent current and the gate charge of the high side MOSFET to be turned on.

The minimum size of the bootstrap capacitor is given by

$$C_{BS} = \frac{Q_{GTOT}}{\Delta V_{BS}}$$

$\Delta V_{BS}$ is the maximum allowable voltage drop at the bootstrap capacitor within a switching period, typically 1 V. It is recommended to keep the voltage drop below the undervoltage lockout (UVLO) of the high side and limit

$$\Delta V_{BS} \leq (V_{CC} - V_f - V_{GS_{min}} - V_{DS_{on}})$$

$V_{GS_{min}} > V_{BS_{UV}}$, $V_{GS_{min}}$ is the minimum gate source voltage we want to maintain and $V_{BS_{UV}}$ is the high-side supply undervoltage negative threshold.

$V_{CC}$ is the IC voltage supply, $V_f$ is bootstrap diode forward voltage and $V_{DS_{on}}$ is drain-source voltage of low side MOSFET.

Please note, that the value $Q_{GTOT}$ may vary to a maximum value based on different factors as explained below and the capacitor shows voltage dependent derating behavior of its capacitance.

The influencing factors contributing $V_{BS}$ to decrease are:

- MOSFET turn on required Gate charge ($Q_G$)
- MOSFET gate-source leakage current ($I_{LK_{GS}}$)
- Floating section quiescent current ($I_{QBS}$)
- Floating section leakage current ($I_{LK}$)
- Bootstrap diode leakage current ($I_{LK_{DIODE}}$)
- Charge required by the internal level shifters ($Q_{LS}$): typical 1nC
- Bootstrap capacitor leakage current ($I_{LK_{CAP}}$)
- High side on time ($T_{HON}$)

Considering the above,

$$Q_{GTOT} = Q_G + Q_{LS} + (I_{QBS} + I_{LK_{GS}} + I_{LK} + I_{LK_{DIODE}} + I_{LK_{CAP}}) * T_{HON}$$
$I_{LK,CAP}$ is only relevant when using an electrolytic capacitor and can be ignored if other types of capacitors are used. It is strongly recommend using at least one low ESR ceramic capacitor (paralleling electrolytic capacitor and low ESR ceramic capacitor may result in an efficient solution).

The above $C_{BS}$ equation is valid for pulse by pulse considerations. It is easy to see, that higher capacitance values are needed, when operating continuously at small duty cycles of low side. The recommended bootstrap capacitance is therefore in the range up to 4.7 μF for most switching frequencies. The performance of the integrated bootstrap diode supports the requirement for small bootstrap capacitances.

### 5.9 Tolerant to negative transients on input pins

Typically the driver's ground pin is connected close to the source pin of the MOSFET or IGBT. The microcontroller which sends the HIN and LIN PWM signals refers to the same ground and in most cases there will be an offset voltage between the microcontroller ground pin and driver ground because of ground bounce. The 2ED210x family can handle negative voltage spikes up to 5 V. The recommended operating level is at negative 4 V with absolute maximum of negative 5 V. Standard half bridge or high-side/low-side drivers only allow negative voltage levels down to -0.3 V. The 2ED210x family has much better noise immunity capability on the input pins.

![Figure 15](image) **Negative voltage tolerance on inputs of up to -5 V**

### 5.10 Negative voltage transient tolerance of VS pin

A common problem in today's high-power switching converters is the transient response of the switch node's voltage as the power switches transition on and off quickly while carrying a large current. A typical 3-phase inverter circuit is shown in Figure 16, here we define the power switches and diodes of the inverter. If the high-side switch (e.g., the IGBT Q1 in Figure 16 and Figure 17) switches from on to off, while the U phase current is flowing to an inductive load, a current commutation occurs from high-side switch (Q1) to the diode (D2) in parallel with the low-side switch of the same inverter leg. At the same instance, the voltage node $V_{S1}$, swings from the positive DC bus voltage to the negative DC bus voltage.
Also when the V phase current flows from the inductive load back to the inverter (see Figure 17 C and D)), and Q4 IGBT switches on, the current commutation occurs from D3 to Q4. At the same instance, the voltage node, VS2, swings from the positive DC bus voltage to the negative DC bus voltage.

However, in a real inverter circuit, the VS voltage swing does not stop at the level of the negative DC bus, rather it swings below the level of the negative DC bus. This undershoot voltage is called “negative VS transient”.

The circuit shown in Figure 18-A depicts one leg of the three phase inverter; Figure 18-B and Figure 18-C show a simplified illustration of the commutation of the current between Q1 and D2. The parasitic inductances in the power circuit from the die bonding to the PCB tracks are lumped together in LC and LE for each IGBT. When the high-side switch is on, VS1 is below the DC+ voltage by the voltage drops associated with the power switch and the parasitic elements of the circuit. When the high-side power switch turns off, the load current momentarily flows in the low-side freewheeling diode due to the inductive load connected to VS1 (the load is not shown in these figures). This current flows from the DC- bus (which is connected to the COM pin of the HVIC) to the load and a negative voltage between VS1 and the DC- Bus is induced (i.e., the COM pin of the HVIC is at a higher potential than the VS pin).
5.11 **NTSOA – Negative Transient Safe Operating Area**

In a typical motor drive system, \( \frac{dV}{dt} \) is typically designed to be in the range of 3 – 5 V / ns. The negative VS transient voltage can exceed this range during some events such as short circuit and over-current shutdown, when \( \frac{di}{dt} \) is greater than in normal operation.

Infineon’s HVICs have been designed for the robustness required in many of today’s demanding applications. An indication of the 2ED2103’s robustness can be seen in Figure 19, where the 2ED2103’s Safe Operating Area is shown at \( V_{BS}=15 \) V based on repetitive negative VS spikes. A negative VS transient voltage falling in the grey area (outside SOA) may lead to IC permanent damage; vice versa unwanted functional anomalies or permanent damage to the IC do not appear if negative VS transients fall inside the SOA.

Even though the 2ED2103S06F has been shown able to handle these large negative VS transient conditions, it is highly recommended that the circuit designer always limit the negative VS transients as much as possible by careful PCB layout and component use.

---

**Figure 18**  
Figure A shows the Parasitic Elements. Figure B shows the generation of \( V_s \) positive. Figure C shows the generation of \( V_s \) negative

**Figure 19**  
Negative VS transient SOA for 2ED2103S06F @ \( V_{BS}=15 \) V
5.12 Higher headroom for input to output signal transmission with logic operation up to -11 V

If there is not enough voltage for the level shifter to transmit a valid signal to the high side. High side driver doesn’t turn on. The level shifter circuit is with respect to COM (refer to Block Diagram on page 4), the voltage from \( V_B \) to COM is the supply voltage of level shifter. Under the condition of \( V_S \) is negative voltage with respect to COM, the voltage of \( V_S - COM \) is decreased, as shown in Figure 20. There is a minimum operational supply voltage of level shifter, if the supply voltage of level shifter is too low, the level shifter cannot pass through HIN signal to HO. If \( V_B - V_S \) voltage is different, the minimum \( V_S \) voltage changes accordingly.

![Figure 20](image)

**Figure 20** Headroom for HV level shifter data transmission

5.13 Maximum switching frequency

The 2ED210x family is capable of switching at higher frequencies as compared to standard half-bridge or high side / low side gate drivers. They are available in PG-DSO-8 package. It is essential to ensure that the component is not thermally overloaded when operating at higher frequencies. This can be checked by means of the thermal resistance junction to ambient and the calculation or measurement of the dissipated power. The thermal resistance is given in the datasheet (section 4) and refers to a specific layout. Changes of this layout may lead to an increased thermal resistance, which will reduce the total dissipated power of the driver IC. One should therefore do temperature measurements in order to avoid thermal overload under application relevant conditions of ambient temperature and housing.

The maximum chip temperature \( T_J \) can be calculated with

\[
T_J = P_d \cdot R_{thJA} + T_{A,\text{max}}, \quad \text{where } T_{A,\text{max}} \text{ is the maximum ambient temperature.}
\]

The dissipated power \( P_d \) by the driver IC is a combination of several sources. These are explained in detail in the application note “Advantages of Infineon’s Silicon on Insulator (SOI) technology based High Voltage Gate Driver ICs (HVICs)”

The output section is the major contributor for the power dissipation of the gate driver IC. The external gate resistors also contribute to the power dissipation of the gate driver IC. The bigger the external gate resistor, the smaller the power dissipation in the gate driver.

The losses of the output section are calculated by means of the total gate charge of the power MOSFET or IGBT it is driving \( Q_{gtot} \), the supply voltage \( V_{CC} \), the switching frequency \( f_p \), and the ext. gate resistor \( R_{gon} \) and \( R_{goff} \). Different cases for turn-on and turn-off must be considered, because many designs use different resistors for turn-on and turn-off. This leads to a specific distribution of losses in respect to the external gate resistor \( R_{gox,\text{ext}} \) and the internal resistances \( (R_{on,\text{int}} \text{ and } R_{off,\text{int}}) \) of the output section.

**Turn on losses:**

\[
P_{don} = \frac{2}{2} \times Q_{gtot} \times V_{CC} \times f_p \times \frac{R_{on,\text{int}}}{R_{on,\text{int}} + R_{gon,\text{ext}}}
\]
Turn off losses: $P_{doff} = \frac{2}{2} \times Q_{g\text{tot}} \times V_{cc} \times f_p \times \frac{R_{off\_int}}{R_{off\_int} + R_{goff\_ext}}$

The above two losses are then added to the remaining static losses within the gate driver IC and we arrive at the below figure as example which estimates the gate driver IC temperature rise when switching a given MOSFET at different switching frequencies.

* Assumptions for above curves: LLC topology, Power switch = IPP60R600P6, $T_a = 25 \, ^\circ C$, $V_{bus} = 400 \, V$, $V_{cc} = 12 \, V$, $R_{gon} = 15 \, \Omega$, $R_{goff} = 12 \, \Omega$

**Figure 21** Estimated temperature rise in the 2ED210x family gate drivers for different switching frequencies when switching CoolMOS™ SJ MOSFETs

### 5.14 PCB layout tips

**Distance between high and low voltage components:** It’s strongly recommended to place the components tied to the floating voltage pins ($V_b$ and $V_s$) near the respective high voltage portions of the device. Please see the Case Outline information in this datasheet for the details.

**Ground Plane:** In order to minimize noise coupling, the ground plane should not be placed under or near the high voltage floating side.

**Gate Drive Loops:** Current loops behave like antennas and are able to receive and transmit EM noise (see Figure 22). In order to reduce the EM coupling and improve the power switch turn on/off performance, the gate drive loops must be reduced as much as possible. Moreover, current can be injected inside the gate drive loop via the IGBT collector-to-gate parasitic capacitance. The parasitic auto-inductance of the gate loop contributes to developing a voltage across the gate-emitter, thus increasing the possibility of a self turn-on effect.

**Figure 22** Avoid antenna loops
Supply Capacitor: It is recommended to place a bypass capacitor ($C_{IN}$) between the $V_{CC}$ and COM pins. A ceramic 1μF ceramic capacitor is suitable for most applications. This component should be placed as close as possible to the pins in order to reduce parasitic elements.

Routing and Placement: Power stage PCB parasitic elements can contribute to large negative voltage transients at the switch node; it is recommended to limit the phase voltage negative transients. In order to avoid such conditions, it is recommended to 1) minimize the high-side emitter to low-side collector distance, and 2) minimize the low-side emitter to negative bus rail stray inductance. However, where negative VS spikes remain excessive, further steps may be taken to reduce the spike. This includes placing a resistor (5 Ω or less) between the VS pin and the switch node (see Figure 23 - A), and in some cases using a clamping diode between COM and $V_S$ (see Figure 23 - B). See DT04-4 at www.infineon.com for more detailed explanations.
