Routing analog signals inside a PSoC® device can be tricky because the desired connections are often not directly available. This application note describes some useful methods to allow configurations that seem impossible, such as the developed example of an eight channel (four channel stereo) audio mixer with adjustment potentiometers.

Contents

Introduction

A PSoC analog user module's input choices are determined by its location. Certain locations have access to Port 0 input multiplexers; others have direct access to the Port 2 inputs. Some only have access to certain adjacent blocks and their column's analog output bus.

Placement of an analog user module requires the correct type of target analog blocks: Continuous Time or Switched Capacitor. Therefore, not all analog user modules have access to a desired signal without another analog module to route it. In some cases – such as routing a Port 0 signal through a PGA to feed it to an ADC – this is a straightforward process.

However, after all four possible PGAs are used and additional simultaneous analog input signals are required, it is confusing to route these signals in, especially to where they are needed.

Some inputs that are typically read with an analog-to-digital converter, such as adjustment potentiometers, can be set up to be read by a timer user module. This frees up valuable analog resources. Some tricks are shown to convert a voltage into a charge time using a single digital pin for discharge and input (one pin per potentiometer). Here is a method to multiplex as many potentiometers as desired sequentially with a single-timer user module.

By configuring generic switched capacitor user modules to act as PGA buffers, an eight channel mixer with both stereo and mono outputs can be completely implemented within a single PSoC device with no external routing.

This mixer includes 15 adjustment potentiometers. There are potentiometers to adjust levels of each of the eight inputs and master adjustments for the left, right, and mono channels. Four more potentiometer inputs control the pre-amp levels of the PGAs in line with some inputs. This

allows the large range adjustment needed for microphones (or other small signal sources) on half of the inputs (specifically, inputs C and D on each side). The current design allows for a sixteenth adjustment potentiometer, but it does not yet have a use.

A serial TX user module is also included and is configured to output a formatted single-line output of all 15 gains. It outputs every couple sets of readings while adjustments are made, at a rate of 57,600 bps. This status display may be viewed with any standard serial terminal.

All Blocks are not created equal

Continuous Time (CT) analog blocks are easy to use: simple analog modules such as PGAs and Comparators go here. All four CT blocks have access to at least four Port 0 input pins (the two center blocks have extra multiplexers allowing connection to any of the eight Port 0 input pins), and the analog column clock has very little effect (if any) on operation.

All four CT blocks are the same and have similar designations; “ACBxy,” where x is the analog row (always 0) and y is the analog column number (0 to 3). These four blocks are along the top row of the analog section, shown in Figure 1.

Switched Capacitor (SC) analog blocks can give the PSoC many capabilities. These blocks can perform such a variety of real time functions that they were given a completely customizable user module, instead of separate modules for each function. This “Generic SCBlock” user module is found as the only entry under the “Generic” category.

SC blocks come in two varieties – Type C and Type D. Originally, in the CY8C25xxx/26xxx PSoC families, these were Type A and Type B. This is detailed in **AN2041**, “Understanding Analog Switched Capacitor Blocks.” Most, if not all of it, still applies to the newer CY8C27x43 and CY8C29x66 devices.

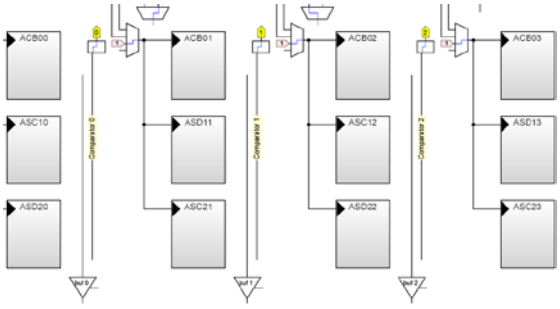
The old Type A blocks have evolved into the new Type C blocks and the old Type B blocks have evolved into the new type D blocks.

Type C SC blocks are designated “ASCxy,” where x is the analog row (1 or 2) and y is the analog column (0 to 3).

Type D SC blocks are designated “ASDxy,” where x is the analog row (1 or 2) and y is the analog column (0 to 3). Type D blocks include an additional option to allow BCap to function as a regular capacitor instead of a switched capacitor – set this BSW to “On” for normal operation.

Type C and D SC blocks are arranged in a checkerboard pattern, beginning with ASC10 as shown in Figure 1.

Figure 1. Analog Block Arrangement



A Switched Capacitor PGA

A Generic SC user module is configured to act as a PGA and amplify audio signals. The SC PGA does not have as large a range of gains as the standard CT PGA, but it is perfect for low and unity gain applications. The standard CT PGA user module provides gains from 0.062x to 48x, whereas the SC PGA created here has a range of 0.062x to only 1.938x (with an FCap value of 16; this range gets smaller and finer when FCap is set to 32). See Table 1 and Table 2 for details.

However, an SC PGA has the unique capability to mix two inputs and control their gains independently. An SC PGA can also invert its non-inverting input. The ratio between FCap and either ACap or BCap controls the gain applied to either the A or B inputs.

Empirically, an analog column clock of 4 MHz is optimum for an audio SC PGA. Faster clocks result in distortion, as the SC blocks do not perform quite as well near their upper limits.

The parameters necessary to create an SC PGA intended for use with AC signals (or audio) from a Generic SC user module are shown for the two types of SC blocks in Figure 2 and Figure 3.

Creating an Eight Channel Mixer

Using CT and SC PGA user modules, all eight simultaneously routable analog input signals (four CT inputs from Port 0 and four end-column SC inputs from Port 2) are mixed into three outputs — Left, Right, and Mono. The basic mixer schematic and internal routing is shown in Figure 5.

The Left output consists of a mix of input channels L_a, L_b, L_c, and L_d. The Right output consists of a mix of input channels R_a, R_b, R_c, and R_d. Mono output is a mix of all eight inputs.

Lc, Ld, Rc, and Rd are routed through CT PGAs before entering the mix and can have a pre-amp gain applied to them. This makes these channels ideal for use as microphone inputs.

The mixer portion of this project operates without logic. The only code required is to initialize the CT PGA modules; the SC PGA modules do not need start commands when their power level is set in the Device Editor to Low, Medium, or High.

If you can preset all your gain settings, then you are done. However, most applications require some real time control over these gains.

Reading Potentiometers without an ADC

Potentiometers are arranged into four banks of four inputs, requiring eight PSoC pins and one timer. Fifteen of the 16 possible potentiometer inputs from this configuration are used in the mixer design, as shown in Figure 6.

The four inputs to the PSoC are on P1[0], P1[1], P1[2], and P1[3]. The four bank control outputs are on P1[4], P1[5], P1[6], and P2[6].

The logic to read all 15 potentiometers sequentially is shown in the flowchart in Figure 7.

First, the potentiometer controlling the gain of L_a is serviced. P1[4] is raised to activate the first bank of inputs and the timer is set to capture the signal on P1[0]. Then, all four input pins are disconnected from their global input buses and changed to drive Open Drain Low outputs.

These outputs are driven low for a brief period to discharge the capacitors. They are then released, set back to High Z digital input drives, and reconnected to their global input busses. Then the timer is started.

A High Z digital input, whether connected to the global input bus or not, acts as an analog comparator referenced to ground with a threshold of approximately 0.500, or ½ of V_{CC}. This allows a timer to measure a potentiometer's position based on how long it takes its capacitor to charge up to this threshold level.

Now that the capacitor is discharged and the timer is started immediately afterwards (when the timer obtains a Capture event), its count is a direct ADC-style reading of the potentiometer. This is accessed after the interrupt through the timer's Compare register.

However, in some cases, the input threshold is reached before the command to start the timer is supplied. This is

not good, as timer user modules do not operate very well with a steady high capture signal. This situation incorrectly results in a minimum reading (zero). Special “Fast Charge” logic is implemented to catch this situation and handle it separately.

The timer is set up to produce a value from 0 to 127 for seven bits of resolution. These seven bits are shifted down to five bits, directly translating into ACap or BCap values for SC PGA gains.

In the case of the CT PGA gain adjustments, these five bits allow access to 32 of the available 33 gains. Because the top gain is so much more significant than the bottom gain, adding one to the CT PGA gain sets the top at 48x (and sets the bottom at 0.12x, excluding 0.06x).

This is done for simplicity and speed, as access to the bottom CT PGA gain is seldom required in this particular application. A separate algorithm (shifting the timer reading down to six bits to interpret the CT PGA gain) could be written if access to all 33 gains is required.

Noise

The PSoC does not create isolated environments for all its modules and blocks. It also does not completely isolate the analog section from the digital section. As a result, many digital functions inject a small amount of audible noise into analog audio streams.

When the TX user module was initially set up to output on P2[7], starting the module (no transmissions) added audible noise into the otherwise quiet inputs on P2[0]–P2[3]. For this reason, the TX uses P1[7] as its output.

The scanning of the potentiometers also injects some unpleasant audible noise into the mix. This noise is much louder when any of the input signals are floating. If all eight inputs are connected, this noise is less noticeable.

The enable button or switch on P2[7] is implemented for this reason. The scanning of the potentiometers is only performed when P2[7] is high; it ceases when P2[7] is low. A button might be labeled “Hold to adjust or Push to update.” A switch might be labeled “Down to lock out changes and Up to adjust.”

There is another situation caused by leakage in this application. The bank select outputs were originally driven as Open Drain High, which should theoretically mix without diodes in the potentiometer scanning circuitry. The After the potentiometer for La is read (and the gain for La adjusted if there is a change), all bank select outputs are released. A short delay then creates a brief dead band.

This process is then repeated for the other seven input controls, three master controls, and four CT PGA pre-amp controls – each time activating the proper bank and reading the appropriate input to access the desired potentiometer.

Every three sets of readings, the applied gains of each of the 15 adjustments are sent out the serial TX port for display on a standard terminal. This allows the user to see exactly what gains are applied, and where. Example output is shown in Figure 4.

Configuration of the PSoC eight channel mixer is shown in Figure 8, Figure 9, Figure 10, and Figure 11 on page 14, 15, 16, and 19 respectively.

bank selects were driven high to select a particular bank, and released to float otherwise. Unfortunately, when floating, the bank outputs sharing Port 1 with the inputs were affected by the various charging capacitors. This resulted in multiple gains being adjusted unintentionally.

For this reason, the bank selects are now strong outputs. They are driven high to select a bank, and low otherwise. To ensure that low drives do not affect the potentiometer readings, blocking diodes (D_1, D_2, D_3, and D_4) are now required on these lines.

Notes

- A simple resistor divider provides the $V_{CC}/2$ AGND, used to bias the AC-coupled inputs.
- The two 100 µF bypass caps (C_{14}, C_{15}) are arranged in series with the supply to facilitate a quick initial charge-up.
- The ACap and BCap settings in the Device Editor have no effect because they are set in the software.

Possibilities and Improvements

The current design requires two programming jumpers to be removed to burn the PSoC in-circuit. This is because P1[0] and P1[1], which are the pins used for programming, have capacitance attached to them. If these capacitors are not removed when attempting in-circuit programming, it

fails. By exchanging these inputs with bank control signals and making the necessary changes to the software, in-circuit programming no longer requires jumpers.

A serial RX user module could be added to allow remote control of the gains. This may be useful in studio situations where multiple users in multiple locations might want to adjust the gains of a single mixer.

A slightly altered version of the eight channel mixer can act as a studio headphone amp, where the artist can select his or her own personal mix of seven line feeds along with an intercom channel back to the control room. PGA_Rd is configured as an intercom with its own output (P0[2]) and can easily be disconnected from SC_Rcd, if necessary.

Even with all the analog functionality present in this eight channel mixer, there is still a single SC block left open. Another analog feature can also be added to this project.

As shown in **AN2412**, “Reverb and Echo with a PSoC-Style FIFO,” a DelSig ADC user module may be used to sample a stream of audio. The single-order DelSig only requires a single SC block (and a digital block), and has its choice of input signals.

With the PSoC adding a bit of reverb and a PRS8 user module representing this altered stream, there may be use for the 16th potentiometer input – adjusting the amount of reverb or echo. This creates another studio application. A singer can control his or her own “scratch mix wetness,” as personal unrecorded reverb adjustments are referred to in the musicians’ world.

Summary

PSoC 1 has routing schemes that seems to have limitations. But we have seen here, how the switched capacitor blocks and the continuous time blocks can be made to simulate the other and thereby achieve the routing we require.

Document Title: Signal Mixing with PSoC® Switched Capacitor Blocks - AN16833

Document Number: 001-16833

Revision	ECN	Orig. of Change	Submission Date	Description of Change
**	2540267	Chris Paiano	07/23/08	New Application Note
*A	2754641	JVY	08/21/09	Changed the document title from “Advanced Internal Analog Routing without Output Buffers” to “Signal Mixing with PSoC Switched Capacitor Blocks”.
*B	3739098	SAMP	09/10/2012	Added Summary. Updated in new template.
*C	4822035	ASRI	07/03/2015	Obsolete document. Completing Sunset Review.
