Short Description

The TDA 4862 integrated circuit controls a boost converter in a way that sinusoidal current is taken from the single-phase line supply and stabilized DC voltage is available at the output. The circuit acts as a harmonic filter which limits the harmonic currents resulting from the pulse charge currents of the capacitor during rectification in a conventional capacitive input rectifier circuit. The power factor which describes the ratio between active and apparent power is almost 1 and line voltage fluctuations are compensated very efficiently, as well.

Technical Description TDA4862

Control Method

The control method of the harmonic filter is based on the physical relationship between current and voltage at the boost converter choke. The transistor does not switch on until the current in the boost converter diode turns zero. This creates triangular currents at a high frequency in the choke as it is principally shown in figure 1, avoiding high-loss reverse recovery currents of the diode. If triangular currents flow through the boost converter choke uninterruptedly, the mean input current calculated over a high-frequency period is exactly half as high as the peak value of the high frequency choke current. If the peak values of the choke current are on an envelope which is proportional to a sinusoidal low-frequency input voltage, a sinusoidal input current will be drawn from the mains after smoothing by means of an RFI suppression filter. The RFI suppression filter is designed in a way that the valid EMI limits at the inputs are not exceeded. Using this control method, the operating frequency of the active harmonic filter changes with the input voltage and the load.

Characteristics

Power Supply and Self-Start

An undervoltage lockout with a turn-on threshold of 11 V typically and a turn-off threshold of 8.5 V typically assures that the IC is functional before the driver output is enabled. In the stand-by state prior to enabling the driver the IC consumes a current of less than 0.2 mA. A startup timer generates a set of pulses for the turn-off flip-flop, if the driver output stays
in low state levels for longer than 150 µs. In order to guarantee safe supply from a current source the supply voltage pin 8 is internally limited to 17 V to ground. Thus, the IC has all functions necessary for low-loss self-start.

Driver output

The driver output has been designed to drive power MOSFET with a current capability of ±500 mA. In order to avoid reverse currents the driver output is equipped with clamping diodes connected to ground and supply voltage with a current rating of 100 mA. In standby state the driver output actively asserts a LOW level with a residual voltage of 1.5 V and 5 mA dissipation current.

Control amplifier

The control amplifier compares the divided output voltage at its inverting input with a highly accurate reference voltage of 2.5 V, with a maximum deviation of less than ±2% over the total temperature range (–40°C < TJ < 150°C), at its non-inverting input. For the purpose of control loop compensation a feedback network is inserted between the amplifier output (pin 2) and its inverting input (pin 1). A feedback design using only one capacitor as an I-controller causes oscillating transient response, because the boost converter, as a controlled current source, with the storage capacitor at its output delays the phase by almost 90° in no-load and in low-load operation. The transient response is more favorable if the control amplifier is designed as a PIT1-controller (see design steps).
The output voltage of the control amplifier ranges from 0.9 V to 4.3 V and can be loaded with a current of 1 mA (source) and 2 mA (sink), respectively. The output voltage of the control amplifier is monitored by a comparator. If the output voltage drops 0.3 V below the reference level of 2.5 V (i.e. reference voltage) of the M2 multiplier input the driver output will be blocked directly via the turn-off flip-flop. This measure guarantees the stability of the output voltage in complete no-load operation, without interferences from offset voltages at the multiplier output or at the comparator input.

The output DC voltage of the boost converter is superimposed by double the mains frequency AC voltage ripple. The amplitude of the superimposed AC voltage depends on the capacity of the storage capacitor and the load. The superimposed AC, which is also fed back via the control amplifier, causes an undesirable modulation of the line current drawn. Therefore the bandwidth of the control amplifier is chosen which is considerably lower than twice the mains-frequency. However, this causes the controller to react slowly to sudden load changes which results in voltage overshoots and output breakdowns.

**Overvoltage control**

If at the boost converter output a higher voltage than the rated output voltage is generated as a result of voltage transients or load rejection, a current flows back from the output voltage divider to the operational amplifier output via the feedback network. This is shown in figure 3. The current $\Delta I$ is measured and in case of a threshold of 30 µA (typ.) is exceeded the multiplier output is controlled to zero potential via a third input M3. This measure causes the input current to be continuously

Figure 3: Examples of the output voltage divider
compensated back, thus avoiding uncontrolled oscillations of the line current drawn, as they usually appear with digital measures.

The switch-off level of the overvoltage control can be adjusted via the internal resistance of the output voltage divider. In normal operation state the voltage at the tap of the divider is 2.5 V (i.e. reference voltage). In case of higher than rated output voltage the excess divider current flows from the tap to the operational amplifier output via the feedback network. The overvoltage control is also guaranteed in the operational phases when the output voltage of the control amplifier reaches the upper limit threshold, because the dissipation current is measured as well. As soon as the output voltage of the control amplifier tends towards the minimum level, the comparator turns off at a level of 2.2 V to guarantee safe no-load operation.

Multiplier
The multiplier generates the turn-off threshold of the current comparator giving consideration to the waveshape of the feed voltage. In a typical application the rectified and divided supply voltage is applied to the input M1 (pin 3). The output voltage of the control amplifier is applied at the input M2 which – under constant load and ideal conditions – appears as DC voltage without superimposed AC shares. At the output of the multiplier a signal in the wave form of the rectified voltage corresponding to input M1 is generated which can be modified in its amplitude via the DC voltage at input M2. Superimposed AC voltage shares at the input M2 cause an undesired modulation of the line current drawn, unless they are part of the dynamic control processes. The level control range of the input M1 is 0 V to 4.0 V, the reference level being 0 V. The level control range of the input M2 is 2.5 V to 4.5 V, the reference level being 2.5 V. For multiplication a further, constant factor $C_m = 0.65 \text{ V}^{-1}$, which is an internal factor of the multiplier, is effective. Its dimension is $\text{V}^{-1}$ in order to comply with the following equation. In this way the current comparator level can be calculated as $V_{Qm} = C_m (V_{pin2} - V_{ref}) V_{pin3}$.

The output voltage of the multiplier is limited to 1.3 V. This measure causes a defined turn-off threshold for current limitation. In this way, dangerous excess currents are avoided which can arise in particular in the case of an expanded input voltage range because the multiplier with its restricted dynamics re-stabilized the current consumption.

Current comparator
The current comparator detects the voltage decline at the shunt which is in the source path of the power MOSFET via its inverting input (pin 4) and which should have an intrinsic inductance as low as possible. When switching on the transistor voltage, spikes are generated at the shunt as a result of the intrinsic inductance of the shunt with turn on and the influence of the driver currents. An integrated low-pass filter suppresses these voltage spikes. As soon as the voltage decline at the shunt reaches
the turn-off threshold defined by the multiplier, the turn-off flip-flop is reset and the driver switches off. The turn-off flip-flop prevents multiple pulses during the switching waveform of the power MOSFET. The turn-off delay time between comparator input and driver output is below 250 ns.

Detector

The detector finds the point of time when the current in the boost converter choke turned zero and then enables the control of a new pulse cycle. After the current comparator triggers the turn-off process and the power MOSFET blocks, the boost converter diode takes over the current. In this case the polarity of the voltage at the choke winding changes in a way that now a higher level voltage level (\(V_{\text{out}}\)) is available at the drain side terminal of the choke compared with the mains rectifier side terminal (level \(V_{\text{in}}\)) of the choke. As soon as the choke current reaches zero and the boost converter diode blocks, the voltage reverses at the drain side terminal of the choke. The voltage at the choke winding turns zero or changes polarity. A second winding (detector winding) on the choke, which has approximately 1/5 of the number of turns compared with the mains winding, permits the change of polarity of the choke voltage to be registered without detrimental influences. Evaluation is effected by the detector function (pin 5) of the IC, with the drain side polarity of the detector winding being measured by means of a hysteresis-determined comparator.

The level for the acceptance of the „MOSFET blocks” command from the turn-off flip-flop and for setting the flip-flop is 2.5 V (i.e. reference voltage) with rising voltage. In case of a voltage decline, which signals the zero crossing of the current, the switching level enabling the driver stage is 1.9 V. The voltage of the detector winding is applied to pin 5 via a high-ohmic resistance (10k to 47k). Clamping structures are available in the IC which limit the voltage at the input to +5 V and +0.6 V, respectively, at 10 mA maximum.

There are cases in which there is no significant detector signal to set the turn-off flip-flop. This may be the case when the supply voltage is switched on, in case of line overvoltage exceeding the output voltage and in no-load and low-load operation, when the voltage controller specifies intermittent operation. In that case a startup generator is activated which supplies a set of pulses to the turn off flip-flop if the driver output stays on LOW-level longer than 150 µs.

Applications of the TDA4862

The following applications demonstrate the good performance of the TDA4862 controlling a power factor preconverter. The design steps indicate the method of the calculation of the components values. Lamp ballast designs as well as a design for switched mode power supplies (SMPS) are given here as
examples. Circuit diagrams and measurement results at different operating conditions establish a good basis for evaluation.

The tables of page 17 ff. also consists of a column called \( I_z \) which contains the values for the surplus current of the auxiliary power supply for the IC bypassed with a 15 V zener diode. The zener current indicates a sufficient IC supply. Therefore it should be low enough to avoid unnecessary losses. There may be also states of operation when the zener current reaches zero. Then the actual supply voltage \( V_{CC} \) of the IC is figured.

Usually a single stage RFI-filter does not accomplish the RFI-standards. Therefore multiple stage RFI-filters are designed into these applications as an example how to suppress resonant oscillations of these filters.

Discontinuous conduction mode always results in a high switching efficiency, because it avoids reverse recovery losses of the boost converter diode. A high power factor, low harmonics, a wide input voltage range and a feedback controlled output voltage are the most important features of a power factor preconverter. The TDA4862 contains all control and monitoring functions to meet these demands.

Boost inductor section

In this section two different approaches for the calculation of the transformer primary inductance $L_p$ are presented. The first one is recommended for a small input voltage range application or for applications with nearly constant output power, e.g. lamp ballasts. Therefore only one example is executed here. The other one is suitable for the demands of wide range applications like they occur in SMPS. All the values of the sections before are still valid.

### 2-Lamp-Ballast SMPS-preconverter

| On-time of power switch: | $T_{on} = L_p \cdot I_{Pk HF} / V_{in}$, $I_{Pk HF} = 2 I_{Ip k}$ |
| Off-time of power switch: | $T_{off} = L_p \cdot I_{Pk HF} / (V_{out} - V_{in})$ |
| Pulse frequency: | $f_p = \frac{1}{T_{on} + T_{off}} = \frac{V_{in} \cdot (V_{out} - V_{in})}{V_{out} \cdot L_p \cdot I_{Pk HF}}$ |

**Design criterion:**

Calculate $L_p$ according to desired range of pulse frequency (e.g. $80 \text{ kHz} < f_p < 110 \text{ kHz}$) at nominal input voltage $V_{in nom}$ and rated output power $P_{out}$

$$L_p = \frac{V_{in nom} \cdot (V_{out} - V_{in nom})}{V_{out} \cdot f_p \cdot I_{Pk HF}} = \frac{V_{in nom} \cdot (V_{out} - V_{in nom}) \cdot \eta \cdot V_{in nom}}{V_{out} \cdot f_p \cdot 2P_{out}}$$

$$= \frac{120 \text{ V} \cdot (230 \text{ V} - 120 \text{ V}) \cdot 0.9 \cdot 120 \text{ V}}{230 \text{ V} \cdot 90 \text{ kHz} \cdot 2 \cdot 75 \text{ W}} = 459 \mu\text{H}$$

Also possible:

Calculate $L_p$ by selecting the on-time $T_{on}$ in the range of $3 \mu\text{s} < T_{on} < 6 \mu\text{s}$

$$L_p = \frac{T_{on} \cdot V_{in nom}}{I_{Pk HF}} = \frac{T_{on} \cdot V_{in nom}^2 \cdot \eta}{2 \cdot P_{out}} = \frac{5 \mu\text{s} \cdot (120\text{V}^2) \cdot 0.9}{2 \cdot 75 \text{ W}} = 432 \mu\text{H}$$

Both inductances will be appropriate.

| SMPS-preconverctor | Design criterion: | Calculate $L_p$ in order to obtain pulse frequencies higher than $25 \text{ kHz}$ at maximum peak input voltage and twice of nominal output power and on minimum peak input voltage and twice of nominal output power

$$L_p < \frac{V_{inP_{max}}^2 \cdot (V_{out} - V_{inP_{max}}) \cdot \eta}{V_{out} \cdot f_p \cdot 2P_{out}} = \frac{(382\text{V})^2 \cdot (410 \text{ V} - 382 \text{ V}) \cdot 0.9}{410 \text{ V} \cdot 25 \text{ kHz} \cdot 2 \cdot 2 \cdot 150 \text{ W}} = 598 \mu\text{H}$$

and

$$L_p < \frac{V_{inP_{min}}^2 \cdot (V_{out} - V_{inP_{min}}) \cdot \eta}{V_{out} \cdot f_p \cdot 2P_{out}} = \frac{(127\text{V})^2 \cdot (410 \text{ V} - 127 \text{ V}) \cdot 0.9}{410 \text{ V} \cdot 25 \text{ kHz} \cdot 2 \cdot 2 \cdot 150 \text{ W}} = 668 \mu\text{H}$$

We therefore select $L_p < 598 \mu\text{H}$
Application

Ballast, \( V_{\text{in rms}} = 120 \) V

\[
L = \frac{(120V)^2 \cdot (230V - 120V) \cdot 0.9}{230V \cdot 90kHz \cdot 2 \cdot P_{\text{OUT}}} = 34.4mH \cdot \frac{W}{W}
\]

\( P_{\text{OUT}} = 75 \) W

\( L = 459 \mu\text{H} \)

Ballast, \( V_{\text{in rms}} = 230 \) V

\[
L = \frac{(230V)^2 \cdot (410V - 230V) \cdot 0.9}{410V \cdot 90kHz \cdot 2 \cdot P_{\text{OUT}}} = 116mH \cdot \frac{W}{W}
\]

\( P_{\text{OUT}} = 55 \) W

\( L = 2.1 \text{ mH} \)

Ballast, \( V_{\text{in rms}} = 277 \) V

\[
L = \frac{(277V)^2 \cdot (480V - 277V) \cdot 0.9}{480V \cdot 90kHz \cdot 2 \cdot P_{\text{OUT}}} = 162mH \cdot \frac{W}{W}
\]

\( P_{\text{OUT}} = 110 \) W

\( L = 1.47 \text{ mH} \)

SMPS, \( V_{\text{in}} = 90 \) V – 270 V

\[
L = \frac{90mH \cdot W}{P_{\text{OUT}}}
\]

\( P_{\text{OUT}} = 150 \) W

\( L = 600\mu\text{H} \)
Operating frequency $f_p$ versus peak input voltage $V_{inPk}$ at constant output power $P_{out}$

$$f_p(V_{inPk\max}) = \frac{V_{inPk\max} \cdot (V_{out} - V_{inPk\max})}{V_{out} \cdot L_p \cdot 2 \cdot I_{inPk\max}} = \frac{V_{inPk\max} \cdot (V_{out} - V_{inPk\max}) \cdot V_{inPk\max}}{V_{out} \cdot L_p \cdot 2 \cdot 2P_{in}} = \frac{V_{inPk\max}^2 \cdot (V_{out} - V_{inPk\max}) \cdot \eta}{V_{out} \cdot L_p \cdot 4 \cdot P_{out}}$$

Operating frequency

$$f_p(\omega t) = \frac{V_{in} \cdot \sqrt{2} \cdot \sin \omega t \cdot (V_{out} - V_{in} \cdot \sqrt{2} \cdot \sin \omega t)}{V_{out} \cdot L_p \cdot 2 \cdot I_{in} \cdot \sqrt{2} \cdot \sin \omega t} = \frac{V_{in} \cdot (V_{out} - V_{in} \cdot \sqrt{2} \cdot \sin \omega t)}{V_{out} \cdot L_p \cdot 2 \cdot I_{in}} = \frac{(V_{in})^2 \cdot \eta}{V_{out} \cdot L_p \cdot 2 \cdot P_{out} \cdot (V_{out} - V_{in} \cdot \sqrt{2} \cdot \sin \omega t)}$$

Example

$$f_p(\omega t) = \frac{(120V)^2 \cdot 0.9}{230V \cdot 450\mu H \cdot 2 \cdot 75W} \cdot (230V - 120V \cdot \sqrt{2} \cdot \sin \omega t)$$

Figure 4 shows the pulse frequency dependent on the peak value of the input voltage for constant output power or constant primary inductance respectively. For example, the lower limit of the input voltage in wide range applications is about 0.3 $V_{out}$. The corresponding pulse frequency is then 40% of the maximum pulse frequency. The upper limit in such applications is about 90% of the output voltage $V_{out}$, which leads to a pulse frequency of about 50% of the maximal value.

It is important, that those two frequencies mentioned above are still above 25 kHz.

![Figure 4: Pulse frequency $f_p$ as a function of the input peak voltage](image-url)
**Output voltage controller:**

Usually a PIT1-design is used in PFC-circuits like it is shown in figure 8. The setting of the values of C1, C2 and R1 should hit the following targets:

- Good suppression of superimposed AC-share of the output voltage which has twice the frequency of the input voltage,
- Good behaviour at load changes or changes of the input voltage,
- Good behaviour at low load conditions.

![Diagram of Output voltage controller with integral component](image)

*Figure 6: Output voltage controller in PIT1-design*
Zero Current Detector

The upper threshold of the ZCD is max. 2.75V. For a continuous operation the difference between output voltage $V_{out}$ and maximum input voltage $V_{inPkmax}$ and the transformation ratio of the inductor windings have to accomplish the following relation

$$(V_{out} - V_{inPkmax}) \cdot \frac{N_{ZCD}}{N_P} > 2.75V$$

The recommended transformation ratio of $N_{ZCD}/N_P = 1/5$ meets a minimal voltage difference of 14 V. If the detector input voltage doesn’t achieve the upper threshold, the IC is operating with the timer frequency.

Auxiliary Power Supply

An obvious way to supply the IC is to use the detector winding. We have to care, that the supply circuit doesn’t influence the detector signal. First, in a simple voltage mode supply, we use a diode, a storage capacitor $C_{10}$ and a current limiting resistor $R_{12}$. We achieve good results in ballast applications with the following design of the transformation ratio:

$\frac{N_{ZCD}}{N_P} = \frac{V_{ZCD}}{V_{out} - V_{innom}}$

$V_{ZCD} = 22V...24V; \quad R_{12} = 220\Omega...270\Omega$

Second in a charge pump supply, we use two diodes, two capacitors $C_{10}, C_{13}$ and one decoupling Resistor $R_{12}$ or a decoupling inductor $L_5$ (lower losses) and a current limiting resistor $R_{12A}$, to avoid burn down at resonance frequency. This method of supply is to prefer in SMPS applications with wide input voltage range.

The supply current increases with the operating frequency at low load and is not dependent on the input voltage. We achieve good results with the following design of the transformation ratio:

$\frac{N_{ZCD}}{N_P} = \frac{V_{ZCD}}{V_{out}} \quad V_{ZCD} = 80V, \quad C_{13} = 3nF...4nF \\
R_{12} = 390\Omega...270\Omega$

Or $C_{13} = 1 \text{nF}...1.5\text{nF}, \quad L_5 = 50 \mu\text{H}...100\mu\text{H}, \quad R_{12A}$ designed with $C_{13}$ and $L_5$ as a low-pass filter of Bessel characteristic.

Figure 7: Auxiliary power supply realized with rectifier (a) and charge pump (b and c)
Applications

L1: 500μH EF25, N27, gap=1mm
W1=75Wdg. 0,40d
W2=15Wdg. 0,22d
Q1: BUZ60 (400V; 1Ω)

Summary of used Nomenclature

**Physics:**

General identifiers:

- $A$ ........ cross area
- $b, B$ ....... magnetic inductance
- $C$ ........ capacitance
- $d, D$ ....... duty cycle
- $f$ .......... frequency
- $i, I$ ........ current
- $L$ .......... inductance
- $N$ .......... number of turns
- $p, P$ ..... power
- $t, T$ ...... time, time-intervals
- $v, V$ ...... voltage
- $W$ ........ energy
- $\eta$ .......... efficiency

Special identifiers:

- $A_L$ ........ inductance factor
- $V_{BRIESE}$ Collector-emitter breakdown voltage of IGBT
- $V_F$....... forward voltage of diodes
- $V_{rms}$.... maximum reverse voltage of diodes

K₁, K₂ .. ferrite core constants

big letters:  contant values and time intervals
small letters: time variant values

**Components:**

- $C$ ........ capacitor
- $D$ ........ diode
- $IC$ ...... integrated circuit
- $L$ .......... inductor
- $R$ ........ resistor
- $TR$....... transformer

**Indices:**

- $AC$ ...... alternating current value
- $DC$ ...... direct current value
- $BE$ ...... basis-emitter value
- $CS$ ....... current sense value
- $J$ .......... Junction value
- $OPTO$ . optocoupler value
- $P$ ........ primary side value
- $Pk$ ...... peak value
- $R$ ....... reflected from secondary to primary side
- $S$ ....... secondary side value
- $Sh$ .... shunt value
- $UVLO$ .. undervoltage lockout value
- $Z$ ........ zener value

- $f_{min}$..... value at minimum pulse frequency
- $i$ .......... running variable
- $in$ ........ input value
- $max$ ....... maximum value
- $min$ ..... minimum value
- $off$ ...... turn-off value
- $on$ ...... turn-on value
- $out$ ...... output value
- $p$ ........ pulsed
- $rip$ ...... ripple value

1,2,3 ... on-going designator
